Abstract

We present Tor, a circuit-based low-latency anonymous communication service. This second-generation Onion Routing system addresses limitations in the original design. Tor adds perfect forward secrecy, congestion control, directory servers, integrity checking, configurable exit policies, and a practical design for rendezvous points. Tor works on the real-world Internet, requires no special privileges or kernel modifications, requires little synchronization or coordination between nodes, and provides a reasonable trade-off between anonymity, usability, and efficiency. We briefly describe our experiences with an international network of more than a dozen hosts. We close with a list of open problems in anonymous communication.

1. Overview

Onion Routing is a distributed overlay network designed to anonymize TCP-based applications like web browsing, secure shell, and instant messaging. Clients choose a path through the network and build a *circuit*, in which each node (or “onion router” or “OR”) in the path knows its predecessor and successor, but no other nodes in the circuit. Traffic flows down the circuit in fixed-size *cells*, which are unwrapped by a symmetric key at each node (like the layers of an onion) and relayed downstream. The Onion Routing project published several design and analysis papers [27, 41, 48, 49]. While a wide area Onion Routing network was deployed briefly, the only long-running public implementation was a fragile proof-of-concept that ran on a single machine. Even this simple deployment processed connections from over sixty thousand distinct IP addresses from all over the world at a rate of about fifty thousand per day. But many critical design and deployment issues were never resolved, and the design has not been updated in several years. Here we describe Tor, a protocol for asynchronous, loosely federated onion routers that provides the following improvements over the old Onion Routing design:

Perfect forward secrecy: Onion Routing was originally

vulnerable to a single hostile node recording traffic and later compromising successive nodes in the circuit and forcing them to decrypt it. Rather than using a single multiply encrypted data structure (an *onion*) to lay each circuit, Tor now uses an incremental or *telescoping* path-building design, where the initiator negotiates session keys with each successive hop in the circuit. Once these keys are deleted, subsequently compromised nodes cannot decrypt old traffic. As a side benefit, onion replay detection is no longer necessary, and the process of building circuits is more reliable, since the initiator knows when a hop fails and can then try extending to a new node.

Separation of “protocol cleaning” from anonymity:

Onion Routing originally required a separate “application proxy” for each supported application protocol—most of which were never written, so many applications were never supported. Tor uses the standard and near-ubiquitous SOCKS [32] proxy interface, allowing us to support most TCP-based programs without modification. Tor now relies on the filtering features of privacy-enhancing application-level proxies such as Privoxy [39], without trying to duplicate those features itself.

No mixing, padding, or traffic shaping (yet): Onion Routing originally called for batching and reordering cells as they arrived, assumed padding between ORs, and in later designs added padding between onion proxies (users) and ORs [27, 41]. Tradeoffs between padding protection and cost were discussed, and *traffic shaping* algorithms were theorized [49] to provide good security without expensive padding, but no concrete padding scheme was suggested. Recent research [1] and deployment experience [4] suggest that this level of resource use is not practical or economical; and even full link padding is still vulnerable [33]. Thus, until we have a proven and convenient design for traffic shaping or low-latency mixing that improves anonymity against a realistic adversary, we leave these strategies out.

Many TCP streams can share one circuit: Onion Routing originally built a separate circuit for each application-level request, but this required multiple public key operations for every request, and also presented a threat to anonymity from building so many circuits; see Section 8.

Tor multiplexes multiple TCP streams along each circuit to improve efficiency and anonymity.

Leaky-pipe circuit topology: Through in-band signaling within the circuit, Tor initiators can direct traffic to nodes partway down the circuit. This novel approach allows traffic to exit the circuit from the middle—possibly frustrating traffic shape and volume attacks based on observing the end of the circuit. (It also allows for long-range padding if future research shows this to be worthwhile.)

Congestion control: Earlier anonymity designs do not address traffic bottlenecks. Unfortunately, typical approaches to load balancing and flow control in overlay networks involve inter-node control communication and global views of traffic. Tor’s decentralized congestion control uses end-to-end acks to maintain anonymity while allowing nodes at the edges of the network to detect congestion or flooding and send less data until the congestion subsides.

Directory servers: The earlier Onion Routing design planned to flood state information through the network—an approach that can be unreliable and complex. Tor takes a simplified view toward distributing this information. Certain more trusted nodes act as *directory servers*: they provide signed directories describing known routers and their current state. Users periodically download them via HTTP.

Variable exit policies: Tor provides a consistent mechanism for each node to advertise a policy describing the hosts and ports to which it will connect. These exit policies are critical in a volunteer-based distributed infrastructure, because each operator is comfortable with allowing different types of traffic to exit the Tor network from his node.

End-to-end integrity checking: The original Onion Routing design did no integrity checking on data. Any node on the circuit could change the contents of data cells as they passed by—for example, to alter a connection request so it would connect to a different webserver, or to ‘tag’ encrypted traffic and look for corresponding corrupted traffic at the network edges [15]. Tor hampers these attacks by verifying data integrity before it leaves the network.

Rendezvous points and hidden services: Tor provides an integrated mechanism for responder anonymity via location-protected servers. Previous Onion Routing designs included long-lived “reply onions” that could be used to build circuits to a hidden server, but these reply onions did not provide forward security, and became useless if any node in the path went down or rotated its keys. In Tor, clients negotiate *rendezvous points* to connect with hidden servers; reply onions are no longer required.

Unlike Freedom [8], Tor does not require OS kernel patches or network stack support. This prevents us from anonymizing non-TCP protocols, but has greatly helped our portability and deployability.

We have implemented all of the above features except rendezvous points. Our source code is available under a free

license, and Tor is not covered by the patent that affected distribution and use of earlier versions of Onion Routing. We have deployed a wide-area alpha network to test the design, to get more experience with usability and users, and to provide a research platform for experimentation. As of this writing, the network stands at eighteen nodes in thirteen distinct administrative domains on two continents.

We review previous work in Section 2, describe our goals and assumptions in Section 3, and then address the above list of improvements in Sections 4 and 5. We summarize in Section 6 how our design stands up to known attacks, and talk about our early deployment experiences in Section 7. We conclude with a list of open problems in Section 8 and future work for the Onion Routing project in Section 9.

2. Related work

Modern anonymity systems date to Chaum’s **Mix-Net** design [10]. Chaum proposed hiding the correspondence between sender and recipient by wrapping messages in layers of public-key cryptography, and relaying them through a path composed of “mixes.” Each mix in turn decrypts, delays, and re-orders messages, before relaying them onward.

Subsequent relay-based anonymity designs have diverged in two main directions. Systems like **Babel** [28], **Mixmaster** [36], and **Mixminion** [15] have tried to maximize anonymity at the cost of introducing comparatively large and variable latencies. Because of this decision, these *high-latency* networks resist strong global adversaries, but introduce too much lag for interactive tasks like web browsing, Internet chat, or SSH connections.

Tor belongs to the second category: *low-latency* designs that try to anonymize interactive network traffic. These systems handle a variety of bidirectional protocols. They also provide more convenient mail delivery than the high-latency anonymous email networks, because the remote mail server provides explicit and timely delivery confirmation. But because these designs typically involve many packets that must be delivered quickly, it is difficult for them to prevent an attacker who can eavesdrop both ends of the communication from correlating the timing and volume of traffic entering the anonymity network with traffic leaving it [45]. These protocols are similarly vulnerable to an active adversary who introduces timing patterns into traffic entering the network and looks for correlated patterns among exiting traffic. Although some work has been done to frustrate these attacks, most designs protect primarily against traffic analysis rather than traffic confirmation (see Section 3.1).

The simplest low-latency designs are single-hop proxies such as the **Anonymizer** [3]: a single trusted server strips the data’s origin before relaying it. These designs are easy to analyze, but users must trust the anonymizing proxy. Concentrating the traffic to this single point increases the

anonymity set (the people a given user is hiding among), but it is vulnerable if the adversary can observe all traffic going into and out of the proxy.

More complex are distributed-trust, circuit-based anonymizing systems. In these designs, a user establishes one or more medium-term bidirectional end-to-end circuits, and tunnels data in fixed-size cells. Establishing circuits is computationally expensive and typically requires public-key cryptography, whereas relaying cells is comparatively inexpensive and typically requires only symmetric encryption. Because a circuit crosses several servers, and each server only knows the adjacent servers in the circuit, no single server can link a user to her communication partners.

The **Java Anon Proxy** (also known as JAP or Web MIXes) uses fixed shared routes known as *cascades*. As with a single-hop proxy, this approach aggregates users into larger anonymity sets, but again an attacker only needs to observe both ends of the cascade to bridge all the system's traffic. The Java Anon Proxy's design calls for padding between end users and the head of the cascade [7]. However, it is not demonstrated whether the current implementation's padding policy improves anonymity.

PipeNet [5, 12], another low-latency design proposed around the same time as Onion Routing, gave stronger anonymity but allowed a single user to shut down the network by not sending. Systems like **ISDN mixes** [38] were designed for other environments with different assumptions.

In P2P designs like **Tarzan** [24] and **MorphMix** [43], all participants both generate traffic and relay traffic for others. These systems aim to conceal whether a given peer originated a request or just relayed it from another peer. While Tarzan and MorphMix use layered encryption as above, **Crowds** [42] simply assumes an adversary who cannot observe the initiator: it uses no public-key encryption, so any node on a circuit can read the circuit's traffic.

Hordes [34] is based on Crowds but also uses multicast responses to hide the initiator. **Herbivore** [25] and **P⁵** [46] go even further, requiring broadcast. These systems are designed primarily for communication between peers, although Herbivore users can make external connections by requesting a peer to serve as a proxy.

Systems like **Freedom** and the original Onion Routing build circuits all at once, using a layered "onion" of public-key encrypted messages, each layer of which provides session keys and the address of the next server in the circuit. Tor as described herein, Tarzan, MorphMix, **Cebolla** [9], and Rennhard's **Anonymity Network** [44] build circuits in stages, extending them one hop at a time. Section 4.2 describes how this approach enables perfect forward secrecy.

Circuit-based anonymity designs must choose which protocol layer to anonymize. They may choose to intercept IP packets directly, and relay them whole (stripping the source address) along the circuit [8, 24]. Alternatively,

like Tor, they may accept TCP streams and relay the data in those streams along the circuit, ignoring the breakdown of that data into TCP segments [43, 44]. Finally, they may accept application-level protocols (such as HTTP) and relay the application requests themselves along the circuit. Making this protocol-layer decision requires a compromise between flexibility and anonymity. For example, a system that understands HTTP, such as Crowds, can strip identifying information from those requests, can take advantage of caching to limit the number of requests that leave the network, and can batch or encode those requests to minimize the number of connections. On the other hand, an IP-level anonymizer can handle nearly any protocol, even ones unforeseen by its designers (though these systems require kernel-level modifications to some operating systems, and so are more complex and less portable). TCP-level anonymity networks like Tor present a middle approach: they are fairly application neutral (so long as the application supports, or can be tunneled across, TCP), but by treating application connections as data streams rather than raw TCP packets, they avoid the well-known inefficiencies of tunneling TCP over TCP [52].

Distributed-trust anonymizing systems need to prevent attackers from adding too many servers and thus compromising user paths. Tor relies on a small set of well-known directory servers, run by independent parties, to decide which nodes can join. Tarzan and MorphMix allow unknown users to run servers, and use a limited resource (like IP addresses) to prevent an attacker from controlling too much of the network. Crowds suggests requiring written, notarized requests from potential crowd members.

Anonymous communication is essential for censorship-resistant systems like Eternity [2], Free Haven [19], Publius [54], and Tangler [53]. Tor's rendezvous points enable connections between mutually anonymous entities; they are a building block for location-hidden servers, which are needed by Eternity and Free Haven.

3. Design goals and assumptions

Goals

Like other low-latency anonymity designs, Tor seeks to frustrate attackers from linking communication partners, or from linking multiple communications to or from a single user. Within this main goal, however, several considerations have directed Tor's evolution.

Deployability: The design must be deployed and used in the real world. Thus it must not be expensive to run (for example, by requiring more bandwidth than volunteers are willing to provide); must not place a heavy liability burden on operators (for example, by allowing attackers to implicate onion routers in illegal activities); and must not be difficult or expensive to implement (for example, by requiring

kernel patches, or separate proxies for every protocol). We also cannot require non-anonymous parties (such as web-sites) to run our software. (Our rendezvous point design does not meet this goal for non-anonymous users talking to hidden servers, however; see Section 4.7.)

Usability: A hard-to-use system has fewer users—and because anonymity systems hide users among users, a system with fewer users provides less anonymity. Usability is thus not only a convenience: it is a security requirement [1, 5]. Tor should therefore not require modifying applications; should not introduce prohibitive delays; and should require users to make as few configuration decisions as possible. Finally, Tor should be easily implemented on all common platforms; we cannot require users to change their operating system to be anonymous. (The current Tor implementation runs on Windows and assorted Unix clones including Linux, FreeBSD, and MacOS X.)

Flexibility: The protocol must be flexible and well-specified, so Tor can serve as a test-bed for future research. Many of the open problems in low-latency anonymity networks, such as generating dummy traffic or preventing Sybil attacks [22], may be solvable independently from the issues solved by Tor. Hopefully future systems will not need to reinvent Tor’s design.

Simple design: The protocol’s design and security parameters must be well-understood. Additional features impose implementation and complexity costs; adding unproven techniques to the design threatens deployability, readability, and ease of security analysis. Tor aims to deploy a simple and stable system that integrates the best accepted approaches to protecting anonymity.

Non-goals

In favoring simple, deployable designs, we have explicitly deferred several possible goals, either because they are solved elsewhere, or because they are not yet solved.

Not peer-to-peer: Tarzan and MorphMix aim to scale to completely decentralized peer-to-peer environments with thousands of short-lived servers, many of which may be controlled by an adversary. This approach is appealing, but still has many open problems [24, 43].

Not secure against end-to-end attacks: Tor does not claim to provide a definitive solution to end-to-end timing or intersection attacks. Some approaches, such as having users run their own onion routers, may help; see Section 8 for more discussion.

No protocol normalization: Tor does not provide *protocol normalization* like Privoxy or the Anonymizer. If senders want anonymity from responders while using complex and variable protocols like HTTP, Tor must be layered with a filtering proxy such as Privoxy to hide differences between clients, and expunge protocol features that leak identity. Note that by this separation Tor can also provide ser-

vices that are anonymous to the network yet authenticated to the responder, like SSH. Similarly, Tor does not integrate tunneling for non-stream-based protocols like UDP; this must be provided by an external service if appropriate.

Not steganographic: Tor does not try to conceal who is connected to the network.

3.1. Threat Model

A global passive adversary is the most commonly assumed threat when analyzing theoretical anonymity designs. But like all practical low-latency systems, Tor does not protect against such a strong adversary. Instead, we assume an adversary who can observe some fraction of network traffic; who can generate, modify, delete, or delay traffic; who can operate onion routers of his own; and who can compromise some fraction of the onion routers.

In low-latency anonymity systems that use layered encryption, the adversary’s typical goal is to observe both the initiator and the responder. By observing both ends, passive attackers can confirm a suspicion that Alice is talking to Bob if the timing and volume patterns of the traffic on the connection are distinct enough; active attackers can induce timing signatures on the traffic to force distinct patterns. Rather than focusing on these *traffic confirmation* attacks, we aim to prevent *traffic analysis* attacks, where the adversary uses traffic patterns to learn which points in the network he should attack.

Our adversary might try to link an initiator Alice with her communication partners, or try to build a profile of Alice’s behavior. He might mount passive attacks by observing the network edges and correlating traffic entering and leaving the network—by relationships in packet timing, volume, or externally visible user-selected options. The adversary can also mount active attacks by compromising routers or keys; by replaying traffic; by selectively denying service to trustworthy routers to move users to compromised routers, or denying service to users to see if traffic elsewhere in the network stops; or by introducing patterns into traffic that can later be detected. The adversary might subvert the directory servers to give users differing views of network state. Additionally, he can try to decrease the network’s reliability by attacking nodes or by performing antisocial activities from reliable nodes and trying to get them taken down—making the network unreliable flushes users to other less anonymous systems, where they may be easier to attack. We summarize in Section 6 how well the Tor design defends against each of these attacks.

4. The Tor Design

The Tor network is an overlay network; each onion router (OR) runs as a normal user-level process without any

special privileges. Each onion router maintains a TLS [17] connection to every other onion router. Each user runs local software called an onion proxy (OP) to fetch directories, establish circuits across the network, and handle connections from user applications. These onion proxies accept TCP streams and multiplex them across the circuits. The onion router on the other side of the circuit connects to the destinations of the TCP streams and relays data.

Each onion router maintains a long-term identity key and a short-term onion key. The identity key is used to sign TLS certificates, to sign the OR's *router descriptor* (a summary of its keys, address, bandwidth, exit policy, and so on), and (by directory servers) to sign directories. The onion key is used to decrypt requests from users to set up a circuit and negotiate ephemeral keys. The TLS protocol also establishes a short-term link key when communicating between ORs. Short-term keys are rotated periodically and independently, to limit the impact of key compromise.

Section 4.1 presents the fixed-size *cells* that are the unit of communication in Tor. We describe in Section 4.2 how circuits are built, extended, truncated, and destroyed. Section 4.3 describes how TCP streams are routed through the network. We address integrity checking in Section 4.4, and resource limiting in Section 4.5. Finally, Section 4.6 talks about congestion control and fairness issues.

4.1. Cells

Onion routers communicate with one another, and with users' OPs, via TLS connections with ephemeral keys. Using TLS conceals the data on the connection with perfect forward secrecy, and prevents an attacker from modifying data on the wire or impersonating an OR.

Traffic passes along these connections in fixed-size cells. Each cell is 512 bytes, and consists of a header and a payload. The header includes a circuit identifier (circID) that specifies which circuit the cell refers to (many circuits can be multiplexed over the single TLS connection), and a command to describe what to do with the cell's payload. (Circuit identifiers are connection-specific: each single circuit has a different circID on each OP/OR or OR/OR connection it traverses.) Based on their command, cells are either *control* cells, which are always interpreted by the node that receives them, or *relay* cells, which carry end-to-end stream data. The control cell commands are: *padding* (currently used for keepalive, but also usable for link padding); *create* or *created* (used to set up a new circuit); and *destroy* (to tear down a circuit).

Relay cells have an additional header (the relay header) after the cell header, containing a streamID (stream identifier: many streams can be multiplexed over a circuit); an end-to-end checksum for integrity checking; the length of the relay payload; and a relay command. The entire con-

tents of the relay header and the relay cell payload are encrypted or decrypted together as the relay cell moves along the circuit, using the 128-bit AES cipher in counter mode to generate a cipher stream. The relay commands are: *relay data* (for data flowing down the stream), *relay begin* (to open a stream), *relay end* (to close a stream cleanly), *relay teardown* (to close a broken stream), *relay connected* (to notify the OP that a relay begin has succeeded), *relay extend* and *relay extended* (to extend the circuit by a hop, and to acknowledge), *relay truncate* and *relay truncated* (to tear down only part of the circuit, and to acknowledge), *relay sendme* (used for congestion control), and *relay drop* (used to implement long-range dummies). We give a visual overview of cell structure plus the details of relay cell structure, and then describe each of these cell types and commands in more detail below.

4.2. Circuits and streams

Onion Routing originally built one circuit for each TCP stream. Because building a circuit can take several tenths of a second (due to public-key cryptography and network latency), this design imposed high costs on applications like web browsing that open many TCP streams.

In Tor, each circuit can be shared by many TCP streams. To avoid delays, users construct circuits preemptively. To limit linkability among their streams, users' OPs build a new circuit periodically if the previous one has been used, and expire old used circuits that no longer have any open streams. OPs consider making a new circuit once a minute: thus even heavy users spend negligible time building circuits, but a limited number of requests can be linked to each other through a given exit node. Also, because circuits are built in the background, OPs can recover from failed circuit creation without delaying streams and thereby harming user experience.

Constructing a circuit

A user's OP constructs circuits incrementally, negotiating a symmetric key with each OR on the circuit, one hop at a time. To begin creating a new circuit, the OP (call her Alice) sends a *create* cell to the first node in her chosen path (call him Bob). (She chooses a new circID C_{AB} not currently used on the connection from her to Bob.) The *create* cell's payload contains the first half of the Diffie-Hellman handshake (g^x), encrypted to the onion key of the OR (call him Bob). Bob responds with a *created* cell containing the second half of the DH handshake, along with a hash of the

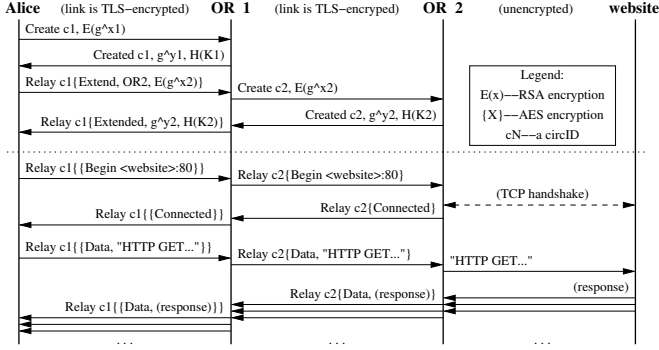

Figure 1. Alice builds a two-hop circuit and begins fetching a web page.

negotiated key $K = g^{xy}$.

Once the circuit has been established, Alice and Bob can send one another relay cells encrypted with the negotiated key.¹ More detail is given in the next section.

To extend the circuit further, Alice sends a *relay extend* cell to Bob, specifying the address of the next OR (call her Carol), and an encrypted g^{x^2} for her. Bob copies the half-handshake into a *create* cell, and passes it to Carol to extend the circuit. (Bob chooses a new circID C_{BC} not currently used on the connection between him and Carol. Alice never needs to know this circID; only Bob associates C_{AB} on his connection with Alice to C_{BC} on his connection with Carol.) When Carol responds with a *created* cell, Bob wraps the payload into a *relay extended* cell and passes it back to Alice. Now the circuit is extended to Carol, and Alice and Carol share a common key $K_2 = g^{x^2y^2}$.

To extend the circuit to a third node or beyond, Alice proceeds as above, always telling the last node in the circuit to extend one hop further.

This circuit-level handshake protocol achieves unilateral entity authentication (Alice knows she’s handshaking with the OR, but the OR doesn’t care who is opening the circuit—Alice uses no public key and is trying to remain anonymous) and unilateral key authentication (Alice and the OR agree on a key, and Alice knows only the OR learns it). It also achieves forward secrecy and key freshness. More formally, the protocol is as follows (where $E_{PK_{Bob}}(\cdot)$ is encryption with Bob’s public key, H is a secure hash function, and $|$ is concatenation):

Alice \rightarrow Bob : $E_{PK_{Bob}}(g^x)$

Bob \rightarrow Alice : $g^y, H(K|“handshake”)$

In the second step, Bob proves that it was he who received g^x , and who chose y . We use PK encryption in the first step (rather than, say, using the first two steps of STS, which has

a signature in the second step) because a single cell is too small to hold both a public key and a signature. Preliminary analysis with the NRL protocol analyzer [35] shows this protocol to be secure (including perfect forward secrecy) under the traditional Dolev-Yao model.

Relay cells

Once Alice has established the circuit (so she shares keys with each OR on the circuit), she can send relay cells. Recall that every relay cell has a streamID that indicates to which stream the cell belongs. Upon receiving a relay cell, an OR looks up the corresponding circuit, and decrypts the relay header and payload with the session key for that circuit. If the cell is headed away from Alice the OR then checks whether the decrypted streamID is recognized—either because it corresponds to an open stream at this OR for the given circuit, or because it is the control streamID (zero). If the OR recognizes the streamID, it accepts the relay cell and processes it as described below. Otherwise, the OR looks up the circID and OR for the next step in the circuit, replaces the circID as appropriate, and sends the decrypted relay cell to the next OR. (If the OR at the end of the circuit receives an unrecognized relay cell, an error has occurred, and the cell is discarded.)

OPs treat incoming relay cells similarly: they iteratively unwrap the relay header and payload with the session keys shared with each OR on the circuit, from the closest to farthest. If at any stage the OP recognizes the streamID, the cell must have originated at the OR whose encryption has just been removed.

To construct a relay cell addressed to a given OR, Alice iteratively encrypts the cell payload (that is, the relay header and payload) with the symmetric key of each hop up to that OR. Because the streamID is encrypted to a different value at each step, only at the targeted OR will it have a meaningful value.² This *leaky pipe* circuit topology allows Alice’s streams to exit at different ORs on a single circuit. Alice may choose different exit points because of their exit policies, or to keep the ORs from knowing that two streams originate from the same person.

When an OR later replies to Alice with a relay cell, it encrypts the cell’s relay header and payload with the single key it shares with Alice, and sends the cell back toward Alice along the circuit. Subsequent ORs add further layers of encryption as they relay the cell back to Alice.

To tear down a circuit, Alice sends a *destroy* control cell. Each OR in the circuit receives the *destroy* cell, closes all streams on that circuit, and passes a new *destroy* cell forward. But just as circuits are built incrementally, they can also be torn down incrementally: Alice can send a *relay truncate* cell to a single OR on a circuit. That OR then

¹Actually, the negotiated key is used to derive two symmetric keys: one for each direction.

²With 48 bits of streamID per cell, the probability of an accidental collision is far lower than the chance of hardware failure.

sends a *destroy* cell forward, and acknowledges with a *relay truncated* cell. Alice can then extend the circuit to different nodes, without signaling to the intermediate nodes (or a limited observer) that she has changed her circuit. Similarly, if a node on the circuit goes down, the adjacent node can send a *relay truncated* cell back to Alice. Thus the “break a node and see which circuits go down” attack [4] is weakened.

4.3. Opening and closing streams

When Alice’s application wants a TCP connection to a given address and port, it asks the OP (via SOCKS) to make the connection. The OP chooses the newest open circuit (or creates one if none is available), and chooses a suitable OR on that circuit to be the exit node (usually the last node, but maybe others due to exit policy conflicts; see Section 5.2.) The OP then opens the stream by sending a *relay begin* cell to the exit node, using a streamID of zero (so the OR will recognize it), containing as its relay payload a new random streamID, the destination address, and the destination port. Once the exit node connects to the remote host, it responds with a *relay connected* cell. Upon receipt, the OP sends a SOCKS reply to notify the application of its success. The OP now accepts data from the application’s TCP stream, packaging it into *relay data* cells and sending those cells along the circuit to the chosen OR.

There’s a catch to using SOCKS, however—some applications pass the alphanumeric hostname to the Tor client, while others resolve it into an IP address first and then pass the IP address to the Tor client. If the application does DNS resolution first, Alice thereby reveals her destination to the remote DNS server, rather than sending the hostname through the Tor network to be resolved at the far end. Common applications like Mozilla and SSH have this flaw.

With Mozilla, the flaw is easy to address: the filtering HTTP proxy called Privoxy gives a hostname to the Tor client, so Alice’s computer never does DNS resolution. But a portable general solution, such as is needed for SSH, is an open problem. Modifying or replacing the local nameserver can be invasive, brittle, and unportable. Forcing the resolver library to do resolution via TCP rather than UDP is hard, and also has portability problems. We could also provide a tool similar to *dig* to perform a private lookup through the Tor network. Currently, we encourage the use of privacy-aware proxies like Privoxy wherever possible.

Closing a Tor stream is analogous to closing a TCP stream: it uses a two-step handshake for normal operation, or a one-step handshake for errors. If the stream closes abnormally, the adjacent node simply sends a *relay teardown* cell. If the stream closes normally, the node sends a *relay end* cell down the circuit. When the other side has sent back its own *relay end* cell, the stream can be torn down. Because all relay cells use layered encryption, only the desti-

nation OR knows that a given relay cell is a request to close a stream. This two-step handshake allows Tor to support TCP-based applications that use half-closed connections.

4.4. Integrity checking on streams

Because the old Onion Routing design used a stream cipher without integrity checking, traffic was vulnerable to a malleability attack: though the attacker could not decrypt cells, any changes to encrypted data would create corresponding changes to the data leaving the network. This weakness allowed an adversary to change a padding cell to a destroy cell; change the destination address in a *relay begin* cell to the adversary’s webserver; or change an FTP command from `dir` to `rm *`. Any adversary who could guess the encrypted content could introduce such corruption in a stream. (Even an external adversary could do this, because the link encryption similarly used a stream cipher.)

Tor uses TLS on its links—its integrity checking protects data from modification by external adversaries. Addressing the insider malleability attack, however, is more complex.

We could do integrity checking of the relay cells at each hop, either by including hashes or by using an authenticating cipher mode like EAX [6], but there are some problems. First, these approaches impose a message-expansion overhead at each hop, and so we would have to either leak the path length or waste bytes by padding to a maximum path length. Second, these solutions can only verify traffic coming from Alice: ORs would not be able to produce suitable hashes for the intermediate hops, since the ORs on a circuit do not know the other ORs’ session keys. Third, we have already accepted that our design is vulnerable to end-to-end timing attacks; tagging attacks performed within the circuit provide no additional information to the attacker.

Thus, we check integrity only at the edges of each stream. When Alice negotiates a key with a new hop, they each initialize a SHA-1 digest with a derivative of that key, thus beginning with randomness that only the two of them know. From then on they each incrementally add to the SHA-1 digest the contents of all relay cells they create, and include with each relay cell the first four bytes of the current digest. Each also keeps a SHA-1 digest of data received, to verify that the received hashes are correct.

To be sure of removing or modifying a cell, the attacker must be able to deduce the current digest state (which depends on all traffic between Alice and Bob, starting with their negotiated key). Attacks on SHA-1 where the adversary can incrementally add to a hash to produce a new valid hash don’t work, because all hashes are end-to-end encrypted across the circuit. The computational overhead of computing the digests is minimal compared to doing the AES encryption performed at each hop of the circuit. We use only four bytes per cell to minimize overhead; the

chance that an adversary will correctly guess a valid hash is acceptably low, given that Alice or Bob tear down the circuit if they receive a bad hash.

4.5. Rate limiting and fairness

Volunteers are more willing to run services that can limit their bandwidth usage. To accommodate them, Tor servers use a token bucket approach [50] to enforce a long-term average rate of incoming bytes, while still permitting short-term bursts above the allowed bandwidth.

Because the Tor protocol generates roughly the same number of outgoing bytes as incoming bytes, it is sufficient in practice to limit only incoming bytes. With TCP streams, however, the correspondence is not one-to-one: relaying a single incoming byte can require an entire 512-byte cell. (We can't just wait for more bytes, because the local application may be waiting for a reply.) Therefore, we treat this case as if the entire cell size had been read, regardless of the fullness of the cell.

Further, inspired by Rennhard et al's design in [44], a circuit's edges can heuristically distinguish interactive streams from bulk streams by comparing the frequency with which they supply cells. We can provide good latency for interactive streams by giving them preferential service, while still giving good overall throughput to the bulk streams. Such preferential treatment presents a possible end-to-end attack, but an adversary observing both ends of the stream can already learn this information through timing attacks.

4.6. Congestion control

Even with bandwidth rate limiting, we still need to worry about congestion, either accidental or intentional. If enough users choose the same OR-to-OR connection for their circuits, that connection can become saturated. For example, an attacker could send a large file through the Tor network to a webserver he runs, and then refuse to read any of the bytes at the webserver end of the circuit. Without some congestion control mechanism, these bottlenecks can propagate back through the entire network. We don't need to reimplement full TCP windows (with sequence numbers, the ability to drop cells when we're full and retransmit later, and so on), because TCP already guarantees in-order delivery of each cell. We describe our response below.

Circuit-level throttling: To control a circuit's bandwidth usage, each OR keeps track of two windows. The *packaging window* tracks how many relay data cells the OR is allowed to package (from incoming TCP streams) for transmission back to the OP, and the *delivery window* tracks how many relay data cells it is willing to deliver to TCP streams outside the network. Each window is initialized (say, to 1000 data cells). When a data cell is packaged or de-

livered, the appropriate window is decremented. When an OR has received enough data cells (currently 100), it sends a *relay sendme* cell towards the OP, with streamID zero. When an OR receives a *relay sendme* cell with streamID zero, it increments its packaging window. Either of these cells increments the corresponding window by 100. If the packaging window reaches 0, the OR stops reading from TCP connections for all streams on the corresponding circuit, and sends no more relay data cells until receiving a *relay sendme* cell.

The OP behaves identically, except that it must track a packaging window and a delivery window for every OR in the circuit. If a packaging window reaches 0, it stops reading from streams destined for that OR.

Stream-level throttling: The stream-level congestion control mechanism is similar to the circuit-level mechanism. ORs and OPs use *relay sendme* cells to implement end-to-end flow control for individual streams across circuits. Each stream begins with a packaging window (currently 500 cells), and increments the window by a fixed value (50) upon receiving a *relay sendme* cell. Rather than always returning a *relay sendme* cell as soon as enough cells have arrived, the stream-level congestion control also has to check whether data has been successfully flushed onto the TCP stream; it sends the *relay sendme* cell only when the number of bytes pending to be flushed is under some threshold (currently 10 cells' worth).

These arbitrarily chosen parameters seem to give tolerable throughput and delay; see Section 7.

4.7. Rendezvous Points and hidden services

Rendezvous points are a building block for *location-hidden services* (also known as *responder anonymity*) in the Tor network. Location-hidden services allow Bob to offer a TCP service, such as a webserver, without revealing his IP address. This type of anonymity protects against distributed DoS attacks: attackers are forced to attack the onion routing network because they do not know Bob's IP address.

Our design for location-hidden servers has the following goals. **Access-controlled:** Bob needs a way to filter incoming requests, so an attacker cannot flood Bob simply by making many connections to him. **Robust:** Bob should be able to maintain a long-term pseudonymous identity even in the presence of router failure. Bob's service must not be tied to a single OR, and Bob must be able to tie his service to new ORs. **Smear-resistant:** A social attacker who offers an illegal or disreputable location-hidden service should not be able to "frame" a rendezvous router by making observers believe the router created that service. **Application-transparent:** Although we require users to run special software to access location-hidden servers, we must not require them to modify their applications.

We provide location-hiding for Bob by allowing him to advertise several onion routers (his *introduction points*) as contact points. He may do this on any robust efficient key-value lookup system with authenticated updates, such as a distributed hash table (DHT) like CFS [11]³ Alice, the client, chooses an OR as her *rendezvous point*. She connects to one of Bob’s introduction points, informs him of her rendezvous point, and then waits for him to connect to the rendezvous point. This extra level of indirection helps Bob’s introduction points avoid problems associated with serving unpopular files directly (for example, if Bob serves material that the introduction point’s community finds objectionable, or if Bob’s service tends to get attacked by network vandals). The extra level of indirection also allows Bob to respond to some requests and ignore others.

In Appendix A we provide a more detailed description of the rendezvous protocol, integration issues, attacks, and related rendezvous work.

5. Other design decisions

5.1. Resource management and denial-of-service

Providing Tor as a public service creates many opportunities for denial-of-service attacks against the network. While flow control and rate limiting (discussed in Section 4.6) prevent users from consuming more bandwidth than routers are willing to provide, opportunities remain for users to consume more network resources than their fair share, or to render the network unusable for others.

First of all, there are several CPU-consuming denial-of-service attacks wherein an attacker can force an OR to perform expensive cryptographic operations. For example, an attacker who sends a *create* cell full of junk bytes can force an OR to perform an RSA decrypt. Similarly, an attacker can fake the start of a TLS handshake, forcing the OR to carry out its (comparatively expensive) half of the handshake at no real computational cost to the attacker.

We have not yet implemented any defenses for these attacks, but several approaches are possible. First, ORs can require clients to solve a puzzle [16] while beginning new TLS handshakes or accepting *create* cells. So long as these tokens are easy to verify and computationally expensive to produce, this approach limits the attack multiplier. Additionally, ORs can limit the rate at which they accept *create* cells and TLS connections, so that the computational work of processing them does not drown out the symmetric cryptography operations that keep cells flowing. This rate limiting could, however, allow an attacker to slow down other users when they build new circuits.

³Rather than rely on an external infrastructure, the Onion Routing network can run the DHT itself. At first, we can run a simple lookup system on the directory servers.

Adversaries can also attack the Tor network’s hosts and network links. Disrupting a single circuit or link breaks all streams passing along that part of the circuit. Users similarly lose service when a router crashes or its operator restarts it. The current Tor design treats such attacks as intermittent network failures, and depends on users and applications to respond or recover as appropriate. A future design could use an end-to-end TCP-like acknowledgment protocol, so that no streams are lost unless the entry or exit point itself is disrupted. This solution would require more buffering at the network edges, however, and the performance and anonymity implications from this extra complexity still require investigation.

5.2. Exit policies and abuse

Exit abuse is a serious barrier to wide-scale Tor deployment. Anonymity presents would-be vandals and abusers with an opportunity to hide the origins of their activities. Attackers can harm the Tor network by implicating exit servers for their abuse. Also, applications that commonly use IP-based authentication (such as institutional mail or web servers) can be fooled by the fact that anonymous connections appear to originate at the exit OR.

We stress that Tor does not enable any new class of abuse. Spammers and other attackers already have access to thousands of misconfigured systems worldwide, and the Tor network is far from the easiest way to launch attacks. But because the onion routers can be mistaken for the originators of the abuse, and the volunteers who run them may not want to deal with the hassle of explaining anonymity networks to irate administrators, we must block or limit the abuse that travels through the Tor network.

To mitigate abuse issues, in Tor, each onion router’s *exit policy* describes to which external addresses and ports the router will connect. On one end of the spectrum are *open exit* nodes that will connect anywhere. On the other end are *middleman* nodes that only relay traffic to other Tor nodes, and *private exit* nodes that only connect to a local host or network. Using a private exit (if one exists) is a more secure way for a client to connect to a given host or network—an external adversary cannot eavesdrop traffic between the private exit and the final destination, and so is less sure of Alice’s destination and activities. Most onion routers in the current network function as *restricted exits* that permit connections to the world at large, but prevent access to certain abuse-prone addresses and services such as SMTP. Additionally, in some cases the OR can authenticate clients to prevent exit abuse without harming anonymity [48].

Many administrators use port restrictions to support only a limited set of services, such as HTTP, SSH, or AIM. This is not a complete solution, of course, since abuse opportunities for these protocols are still well known.

We have not yet encountered any abuse in the deployed network, but if we do we should consider using proxies to clean traffic for certain protocols as it leaves the network. For example, much abusive HTTP behavior (such as exploiting buffer overflows or well-known script vulnerabilities) can be detected in a straightforward manner. Similarly, one could run automatic spam filtering software (such as SpamAssassin) on email exiting the OR network.

ORs may also rewrite exiting traffic to append headers or other information indicating that the traffic has passed through an anonymity service. This approach is commonly used by email-only anonymity systems. ORs can also run on servers with hostnames like *anonymous* to further alert abuse targets to the nature of the anonymous traffic.

A mixture of open and restricted exit nodes allows the most flexibility for volunteers running servers. But while having many middleman nodes provides a large and robust network, having only a few exit nodes reduces the number of points an adversary needs to monitor for traffic analysis, and places a greater burden on the exit nodes. This tension can be seen in the Java Anon Proxy cascade model, wherein only one node in each cascade needs to handle abuse complaints—but an adversary only needs to observe the entry and exit of a cascade to perform traffic analysis on all that cascade’s users. The hydra model (many entries, few exits) presents a different compromise: only a few exit nodes are needed, but an adversary needs to work harder to watch all the clients; see Section 9.

Finally, we note that exit abuse must not be dismissed as a peripheral issue: when a system’s public image suffers, it can reduce the number and diversity of that system’s users, and thereby reduce the anonymity of the system itself. Like usability, public perception is a security parameter. Sadly, preventing abuse of open exit nodes is an unsolved problem, and will probably remain an arms race for the foreseeable future. The abuse problems faced by Princeton’s CoDeeN project [37] give us a glimpse of likely issues.

5.3. Directory Servers

First-generation Onion Routing designs [8, 41] used in-band network status updates: each router flooded a signed statement to its neighbors, which propagated it onward. But anonymizing networks have different security goals than typical link-state routing protocols. For example, delays (accidental or intentional) that can cause different parts of the network to have different views of link-state and topology are not only inconvenient: they give attackers an opportunity to exploit differences in client knowledge. We also worry about attacks to deceive a client about the router membership list, topology, or current network state. Such *partitioning attacks* on client knowledge help an adversary to efficiently deploy resources against a target [15].

Tor uses a small group of redundant, well-known onion routers to track changes in network topology and node state, including keys and exit policies. Each such *directory server* acts as an HTTP server, so clients can fetch current network state and router lists, and so other ORs can upload state information. Onion routers periodically publish signed statements of their state to each directory server. The directory servers combine this information with their own views of network liveness, and generate a signed description (a *directory*) of the entire network state. Client software is preloaded with a list of the directory servers and their keys, to bootstrap each client’s view of the network.

When a directory server receives a signed statement for an OR, it checks whether the OR’s identity key is recognized. Directory servers do not automatically advertise unrecognized ORs. (If they did, an adversary could take over the network by creating many servers [22].) Instead, new nodes must be approved by the directory server administrator before they are included. Mechanisms for automated node approval are an area of active research, and are discussed more in Section 8.

Of course, a variety of attacks remain. An adversary who controls a directory server can track clients by providing them different information—perhaps by listing only nodes under its control, or by informing only certain clients about a given node. Even an external adversary can exploit differences in client knowledge: clients who use a node listed on one directory server but not the others are vulnerable.

Thus these directory servers must be synchronized and redundant, so that they can agree on a common directory. Clients should only trust this directory if it is signed by a threshold of the directory servers.

The directory servers in Tor are modeled after those in Mixminion [15], but our situation is easier. First, we make the simplifying assumption that all participants agree on the set of directory servers. Second, while Mixminion needs to predict node behavior, Tor only needs a threshold consensus of the current state of the network.

Tor directory servers build a consensus directory through a simple four-round broadcast protocol. In round one, each server dates and signs its current opinion, and broadcasts it to the other directory servers; then in round two, each server rebroadcasts all the signed opinions it has received. At this point all directory servers check to see whether any server has signed multiple opinions in the same period. Such a server is either broken or cheating, so the protocol stops and notifies the administrators, who either remove the cheater or wait for the broken server to be fixed. If there are no discrepancies, each directory server then locally computes an algorithm (described below) on the set of opinions, resulting in a uniform shared directory. In round three servers sign this directory and broadcast it; and finally in round four the servers rebroadcast the directory and all the signatures. If

any directory server drops out of the network, its signature is not included on the final directory.

The rebroadcast steps ensure that a directory server is heard by either all of the other servers or none of them, even when some links are down (assuming that any two directory servers can talk directly or via a third). Broadcasts are feasible because there are relatively few directory servers (currently 3, but we expect as many as 9 as the network scales). Computing the shared directory locally is a straightforward threshold voting process: we include an OR if a majority of directory servers believe it to be good.

To avoid attacks where a router connects to all the directory servers but refuses to relay traffic from other routers, the directory servers must build circuits and use them to anonymously test router reliability [18]. Unfortunately, this defense is not yet designed or implemented.

Using directory servers is simpler and more flexible than flooding. Flooding is expensive, and complicates the analysis when we start experimenting with non-clique network topologies. Signed directories can be cached by other onion routers, so directory servers are not a performance bottleneck when we have many users, and do not aid traffic analysis by forcing clients to periodically announce their existence to any central point.

6. Attacks and Defenses

Below we summarize a variety of attacks, and discuss how well our design withstands them.

Passive attacks

Observing user traffic patterns. Observing a user's connection will not reveal her destination or data, but it will reveal traffic patterns (both sent and received). Profiling via user connection patterns requires further processing, because multiple application streams may be operating simultaneously or in series over a single circuit.

Observing user content. While content at the user end is encrypted, connections to responders may not be (indeed, the responding website itself may be hostile). While filtering content is not a primary goal of Onion Routing, Tor can directly use Privoxy and related filtering services to anonymize application data streams.

Option distinguishability. We allow clients to choose configuration options. For example, clients concerned about request linkability should rotate circuits more often than those concerned about traceability. Allowing choice may attract users with different needs; but clients who are in the minority may lose more anonymity by appearing distinct than they gain by optimizing their behavior [1].

End-to-end timing correlation. Tor only minimally hides such correlations. An attacker watching patterns of traffic at the initiator and the responder will be able to confirm the

correspondence with high probability. The greatest protection currently available against such confirmation is to hide the connection between the onion proxy and the first Tor node, by running the OP on the Tor node or behind a firewall. This approach requires an observer to separate traffic originating at the onion router from traffic passing through it: a global observer can do this, but it might be beyond a limited observer's capabilities.

End-to-end size correlation. Simple packet counting will also be effective in confirming endpoints of a stream. However, even without padding, we have some limited protection: the leaky pipe topology means different numbers of packets may enter one end of a circuit than exit at the other.

Website fingerprinting. All the effective passive attacks above are traffic confirmation attacks, which puts them outside our design goals. There is also a passive traffic analysis attack that is potentially effective. Rather than searching exit connections for timing and volume correlations, the adversary may build up a database of "fingerprints" containing file sizes and access patterns for targeted websites. He can later confirm a user's connection to a given site simply by consulting the database. This attack has been shown to be effective against SafeWeb [29]. It may be less effective against Tor, since streams are multiplexed within the same circuit, and fingerprinting will be limited to the granularity of cells (currently 512 bytes). Additional defenses could include larger cell sizes, padding schemes to group websites into large sets, and link padding or long-range dummies.⁴

Active attacks

Compromise keys. An attacker who learns the TLS session key can see control cells and encrypted relay cells on every circuit on that connection; learning a circuit session key lets him unwrap one layer of the encryption. An attacker who learns an OR's TLS private key can impersonate that OR for the TLS key's lifetime, but he must also learn the onion key to decrypt *create* cells (and because of perfect forward secrecy, he cannot hijack already established circuits without also compromising their session keys). Periodic key rotation limits the window of opportunity for these attacks. On the other hand, an attacker who learns a node's identity key can replace that node indefinitely by sending new forged descriptors to the directory servers.

Iterated compromise. A roving adversary who can compromise ORs (by system intrusion, legal coercion, or extralegal coercion) could march down the circuit compromising the nodes until he reaches the end. Unless the adversary can complete this attack within the lifetime of the circuit,

⁴Note that this fingerprinting attack should not be confused with the much more complicated latency attacks of [5], which require a fingerprint of the latencies of all circuits through the network, combined with those from the network edges to the target user and the responder website.

however, the ORs will have discarded the necessary information before the attack can be completed. (Thanks to the perfect forward secrecy of session keys, the attacker cannot force nodes to decrypt recorded traffic once the circuits have been closed.) Additionally, building circuits that cross jurisdictions can make legal coercion harder—this phenomenon is commonly called “jurisdictional arbitrage.” The Java Anon Proxy project recently experienced the need for this approach, when a German court forced them to add a back-door to all of their nodes [51].

Run a recipient. An adversary running a webserver trivially learns the timing patterns of users connecting to it, and can introduce arbitrary patterns in its responses. End-to-end attacks become easier: if the adversary can induce users to connect to his webserver (perhaps by advertising content targeted to those users), she now holds one end of their connection. There is also a danger that application protocols and associated programs can be induced to reveal information about the initiator. Tor depends on Privoxy and similar protocol cleaners to solve this latter problem.

Run an onion proxy. It is expected that end users will nearly always run their own local onion proxy. However, in some settings, it may be necessary for the proxy to run remotely—typically, in institutions that want to monitor the activity of those connecting to the proxy. Compromising an onion proxy compromises all future connections through it.

DoS non-observed nodes. An observer who can only watch some of the Tor network can increase the value of this traffic by attacking non-observed nodes to shut them down, reduce their reliability, or persuade users that they are not trustworthy. The best defense here is robustness.

Run a hostile OR. In addition to being a local observer, an isolated hostile node can create circuits through itself, or alter traffic patterns to affect traffic at other nodes. Nonetheless, a hostile node must be immediately adjacent to both endpoints to compromise the anonymity of a circuit. If an adversary can run multiple ORs, and can persuade the directory servers that those ORs are trustworthy and independent, then occasionally some user will choose one of those ORs for the start and another as the end of a circuit. If an adversary controls $m > 1$ out of N nodes, he can to correlate at most $(\frac{m}{N})^2$ of the traffic in this way—although an adversary could possibly attract a disproportionately large amount of traffic by running an OR with a permissive exit policy, or by degrading the reliability of other routers.

Introduce timing into messages. This is simply a stronger version of passive timing attacks already discussed earlier.

Tagging attacks. A hostile node could “tag” a cell by altering it. If the stream were, for example, an unencrypted request to a Web site, the garbled content coming out at the appropriate time would confirm the association. However, integrity checks on cells prevent this attack.

Replace contents of unauthenticated protocols. When re-

laying an unauthenticated protocol like HTTP, a hostile exit node can impersonate the target server. Clients should prefer protocols with end-to-end authentication.

Replay attacks. Some anonymity protocols are vulnerable to replay attacks. Tor is not; replaying one side of a handshake will result in a different negotiated session key, and so the rest of the recorded session can’t be used.

Smear attacks. An attacker could use the Tor network for socially disapproved acts, to bring the network into disrepute and get its operators to shut it down. Exit policies reduce the possibilities for abuse, but ultimately the network requires volunteers who can tolerate some political heat.

Distribute hostile code. An attacker could trick users into running subverted Tor software that did not, in fact, anonymize their connections—or worse, could trick ORs into running weakened software that provided users with less anonymity. We address this problem (but do not solve it completely) by signing all Tor releases with an official public key, and including an entry in the directory that lists which versions are currently believed to be secure. To prevent an attacker from subverting the official release itself (through threats, bribery, or insider attacks), we provide all releases in source code form, encourage source audits, and frequently warn our users never to trust any software (even from us) that comes without source.

Directory attacks

Destroy directory servers. If a few directory servers disappear, the others still decide on a valid directory. So long as any directory servers remain in operation, they will still broadcast their views of the network and generate a consensus directory. (If more than half are destroyed, this directory will not, however, have enough signatures for clients to use it automatically; human intervention will be necessary for clients to decide whether to trust the resulting directory.)

Subvert a directory server. By taking over a directory server, an attacker can partially influence the final directory. Since ORs are included or excluded by majority vote, the corrupt directory can at worst cast a tie-breaking vote to decide whether to include marginal ORs. It remains to be seen how often such marginal cases occur in practice.

Subvert a majority of directory servers. An adversary who controls more than half the directory servers can include as many compromised ORs in the final directory as he wishes. We must ensure that directory server operators are independent and attack-resistant.

Encourage directory server dissent. The directory agreement protocol assumes that directory server operators agree on the set of directory servers. An adversary who can persuade some of the directory server operators to distrust one another could split the quorum into mutually hostile camps, thus partitioning users based on which directory they use. Tor does not address this attack.

Trick the directory servers into listing a hostile OR. Our threat model explicitly assumes directory server operators will be able to filter out most hostile ORs.

Convince the directories that a malfunctioning OR is working. In the current Tor implementation, directory servers assume that an OR is running correctly if they can start a TLS connection to it. A hostile OR could easily subvert this test by accepting TLS connections from ORs but ignoring all cells. Directory servers must actively test ORs by building circuits and streams as appropriate. The tradeoffs of a similar approach are discussed in [18].

7. Early experiences: Tor in the Wild

As of mid-January 2004, the Tor network consists of 18 nodes (16 in the US, 2 in Europe), and more are joining each week as the code matures.⁵ Each node has at least a 768Kb/768Kb connection, and many have 10Mb. The number of users varies (and of course, it's hard to tell for sure), but we sometimes have several hundred users—administrators at several companies have begun sending their entire departments' web traffic through Tor, to block other divisions of their company from reading their traffic. Tor users have reported using the network for web browsing, FTP, IRC, AIM, Kazaa, and SSH.

Each Tor node currently processes roughly 800,000 relay cells (a bit under half a gigabyte) per week. On average, about 80% of each 500-byte payload is full for cells going back to the client, whereas about 40% is full for cells coming from the client. (The difference arises because most of the network's traffic is web browsing.) Interactive traffic like SSH brings down the average a lot—once we have more experience, and assuming we can resolve the anonymity issues, we may partition traffic into two relay cell sizes: one to handle bulk traffic and one for interactive traffic.

Based in part on our restrictive default exit policy (we reject SMTP requests) and our low profile, we have had no abuse issues since the network was deployed in October 2003. Our slow growth rate gives us time to add features, resolve bugs, and get a feel for what users actually want from an anonymity system. Even though having more users would bolster our anonymity sets, we are not eager to attract the Kazaa or warez communities—we feel that we must build a reputation for privacy, human rights, research, and other socially laudable activities.

As for performance, profiling shows that Tor spends almost all its CPU time in AES, which is fast. Current latency is attributable to two factors. First, network latency is crit-

⁵For comparison, the current remailer network has about 30 reliable nodes. We haven't asked PlanetLab to provide Tor nodes, since their AUP wouldn't allow exit nodes (see also [37]) and because we aim to build a long-term community of node operators and developers.

ical: we are intentionally bouncing traffic around the world several times. Second, our end-to-end congestion control algorithm focuses on protecting volunteer servers from accidental DoS rather than on optimizing performance. To quantify these effects, we did some informal tests using a network of 4 nodes on the same machine (a heavily loaded 1GHz Athlon). We downloaded a 60 megabyte file from `debian.org` every 30 minutes for 54 hours (108 sample points). It arrived in about 300 seconds on average, compared to 210s for a direct download. We ran a similar test on the production Tor network, fetching the front page of `cnn.com` (55 kilobytes): while a direct download consistently took about 0.3s, the performance through Tor was highly variable. Some downloads were as fast as 0.6s, with a median at 2.7s, and 80% finishing within 5.7s. It seems that as the network expands, the chance of building a slow circuit (one that includes a slow or heavily loaded node or link) is increasing. On the other hand, as our users remain satisfied with this increased latency, we can address our performance incrementally as we proceed with development.⁶

Indeed, the Tor design aims foremost to provide a security research platform; performance only needs to be sufficient to retain users [1, 5]. We can tweak the congestion control parameters to provide faster throughput at the cost of larger buffers at each node; adding the heuristics mentioned in Section 4.5 to favor low-volume streams may also help. More research remains to find the right balance.

Although Tor's clique topology and full-visibility directories present scaling problems, we still expect the network to support a few hundred nodes and maybe 10,000 users before we're forced to become more distributed. With luck, the experience we gain running the current topology will help us choose among alternatives when the time comes.

8. Open Questions in Low-latency Anonymity

In addition to the non-goals in Section 3, many other questions must be solved before we can be confident of Tor's security.

Many of these open issues are questions of balance. For example, how often should users rotate to fresh circuits? Frequent rotation is inefficient, expensive, and may lead to intersection attacks and predecessor attacks [55], but infrequent rotation makes the user's traffic linkable. Besides opening fresh circuits, clients can also exit from the middle of the circuit, or truncate and re-extend the circuit. More analysis is needed to determine the proper tradeoff.

How should we choose path lengths? If Alice only ever uses two hops, then both ORs can be certain that by colluding they will learn about Alice and Bob. In our current

⁶For example, we have just begun pushing a pipelining patch to the production network that seems to decrease latency for medium-to-large files; we will present revised benchmarks as they become available.

approach, Alice always chooses at least three nodes unrelated to herself and her destination. Should Alice choose a random path length (say, increasing it from a geometric distribution) to foil an attacker who uses timing to learn that he is the fifth hop and thus concludes that both Alice and the responder are on ORs?

Throughout this paper, we have assumed that end-to-end traffic confirmation will immediately and automatically defeat a low-latency anonymity system. Even high-latency anonymity systems can be vulnerable to end-to-end traffic confirmation, if the traffic volumes are high enough, and if users' habits are sufficiently distinct [14, 31]. Can anything be done to make low-latency systems resist these attacks as well as high-latency systems? Tor already makes some effort to conceal the starts and ends of streams by wrapping long-range control commands in identical-looking relay cells. Link padding could frustrate passive observers who count packets; long-range padding could work against observers who own the first hop in a circuit. But more research remains to find an efficient and practical approach. Volunteers prefer not to run constant-bandwidth padding; but no convincing traffic shaping approach has been specified. Recent work on long-range padding [33] shows promise. One could also try to reduce correlation in packet timing by batching and re-ordering packets, but it is unclear whether this could improve anonymity without introducing so much latency as to render the network unusable.

A cascade topology may better defend against traffic confirmation by aggregating users, and making padding and mixing more affordable. Does the hydra topology (many input nodes, few output nodes) work better against some adversaries? Are we going to get a hydra anyway because most nodes will be middleman nodes?

Common wisdom suggests that Alice should run her own OR for best anonymity, because traffic coming from her node could plausibly have come from elsewhere. How much mixing does this approach need? Is it immediately beneficial because of real-world adversaries that can't observe Alice's router, but can run routers of their own?

To scale to many users, and to prevent an attacker from observing the whole network, it may be necessary to support far more servers than Tor currently anticipates. This introduces several issues. First, if approval by a central set of directory servers is no longer feasible, what mechanism should be used to prevent adversaries from signing up many colluding servers? Second, if clients can no longer have a complete picture of the network, how can they perform discovery while preventing attackers from manipulating or exploiting gaps in their knowledge? Third, if there are too many servers for every server to constantly communicate with every other, which non-clique topology should the network use? (Restricted-route topologies promise comparable anonymity with better scalability [13], but whatever topol-

ogy we choose, we need some way to keep attackers from manipulating their position within it [21].) Fourth, if no central authority is tracking server reliability, how do we stop unreliable servers from making the network unusable? Fifth, do clients receive so much anonymity from running their own ORs that we should expect them all to do so [1], or do we need another incentive structure to motivate them? Tarzan and MorphMix present possible solutions.

When a Tor node goes down, all its circuits (and thus streams) must break. Will users abandon the system because of this brittleness? How well does the method in Section 5.1 allow streams to survive node failure? If affected users rebuild circuits immediately, how much anonymity is lost? It seems the problem is even worse in a peer-to-peer environment—such systems don't yet provide an incentive for peers to stay connected when they're done retrieving content, so we would expect a higher churn rate.

9. Future Directions

Tor brings together many innovations into a unified deployable system. The next immediate steps include:

Scalability: Tor's emphasis on deployability and design simplicity has led us to adopt a clique topology, semi-centralized directories, and a full-network-visibility model for client knowledge. These properties will not scale past a few hundred servers. Section 8 describes some promising approaches, but more deployment experience will be helpful in learning the relative importance of these bottlenecks.

Bandwidth classes: This paper assumes that all ORs have good bandwidth and latency. We should instead adopt the MorphMix model, where nodes advertise their bandwidth level (DSL, T1, T3), and Alice avoids bottlenecks by choosing nodes that match or exceed her bandwidth. In this way DSL users can usefully join the Tor network.

Incentives: Volunteers who run nodes are rewarded with publicity and possibly better anonymity [1]. More nodes means increased scalability, and more users can mean more anonymity. We need to continue examining the incentive structures for participating in Tor. Further, we need to explore more approaches to limiting abuse, and understand why most people don't bother using privacy systems.

Cover traffic: Currently Tor omits cover traffic—its costs in performance and bandwidth are clear but its security benefits are not well understood. We must pursue more research on link-level cover traffic and long-range cover traffic to determine whether some simple padding method offers provable protection against our chosen adversary.

Caching at exit nodes: Perhaps each exit node should run a caching web proxy [47], to improve anonymity for cached pages (Alice's request never leaves the Tor network), to improve speed, and to reduce bandwidth cost. On the other hand, forward security is weakened because caches

constitute a record of retrieved files. We must find the right balance between usability and security.

Better directory distribution: Clients currently download a description of the entire network every 15 minutes. As the state grows larger and clients more numerous, we may need a solution in which clients receive incremental updates to directory state. More generally, we must find more scalable yet practical ways to distribute up-to-date snapshots of network status without introducing new attacks.

Implement location-hidden services: The design in Appendix A has not yet been implemented. While doing so we are likely to encounter additional issues that must be resolved, both in terms of usability and anonymity.

Further specification review: Our public byte-level specification [20] needs external review. We hope that as Tor is deployed, more people will examine its specification.

Multisystem interoperability: We are currently working with the designer of MorphMix to unify the specification and implementation of the common elements of our two systems. So far, this seems to be relatively straightforward. Interoperability will allow testing and direct comparison of the two designs for trust and scalability.

Wider-scale deployment: The original goal of Tor was to gain experience in deploying an anonymizing overlay network, and learn from having actual users. We are now at a point in design and development where we can start deploying a wider network. Once we have many actual users, we will doubtlessly be better able to evaluate some of our design decisions, including our robustness/latency tradeoffs, our performance tradeoffs (including cell size), our abuse-prevention mechanisms, and our overall usability.

Acknowledgments

We thank Peter Palfrader, Geoff Goodell, Adam Shostack, Joseph Sokol-Margolis, John Bashinski, and Zack Brown for editing and comments; Matej Pfajfar, Andrei Serjantov, Marc Rennhard for design discussions; Bram Cohen for congestion control discussions; Adam Back for suggesting telescoping circuits; and Cathy Meadows for formal analysis of the *extend* protocol. This work has been supported by ONR and DARPA.

A. Rendezvous points and hidden services

In this appendix we provide specifics about the rendezvous points of Section 4.7. The following steps are performed on behalf of Alice and Bob by their local OPs; application integration is described more fully below.

- Bob chooses some introduction points, and advertises them on the DHT. He can add more later.
- Bob builds a circuit to each of his introduction points, and waits for requests.
- Alice learns about Bob’s service out of band (perhaps Bob told her, or she found it on a website). She retrieves the details of Bob’s service from the DHT.
- Alice chooses an OR as the rendezvous point (RP) for this transaction. She builds a circuit to the RP, and gives it a rendezvous cookie to recognize Bob.
- Alice opens an anonymous stream to one of Bob’s introduction points, and gives it a message (encrypted to Bob’s public key) telling it about herself, her RP and rendezvous cookie, and the start of a DH handshake. The introduction point sends the message to Bob.
- If Bob wants to talk to Alice, he builds a circuit to Alice’s RP and sends the rendezvous cookie, the second half of the DH handshake, and a hash of the session key they now share. By the same argument as in Section 4.2, Alice knows she shares the key only with Bob.
- The RP connects Alice’s circuit to Bob’s. Note that RP can’t recognize Alice, Bob, or the data they transmit.
- Alice sends a *relay begin* cell along the circuit. It arrives at Bob’s OP, which connects to Bob’s webserver.
- An anonymous stream has been established, and Alice and Bob communicate as normal.

When establishing an introduction point, Bob provides the onion router with a public “introduction” key. The hash of this public key identifies a unique service, and (since Bob signs his messages) prevents anybody else from usurping Bob’s introduction point in the future. Bob uses the same public key to establish the other introduction points for his service, and periodically refreshes his entry in the DHT.

The message that Alice gives the introduction point includes a hash of Bob’s public key and an optional initial authorization token (the introduction point can do prescreening, for example to block replays). Her message to Bob may include an end-to-end authorization token so Bob can choose whether to respond. The authorization tokens can be used to provide selective access: important users can get uninterrupted access. During normal situations, Bob’s service might simply be offered directly from mirrors, while Bob gives out tokens to high-priority users. If the mirrors are knocked down, those users can switch to accessing Bob’s service via the Tor rendezvous system.

Bob’s introduction points are themselves subject to DoS—he must open many introduction points or risk such an attack. He can provide selected users with a current list or future schedule of unadvertised introduction points; this is most practical if there is a stable and large group of introduction points available. Bob could also give secret public keys for consulting the DHT. All of these approaches limit exposure even when some selected users collude in the DoS.

A.1. Integration with user applications

Bob configures his onion proxy to know the local IP address and port of his service, a strategy for authorizing clients, and a public key. Bob publishes the public key, an expiration time, and the current introduction points for his service into the DHT, indexed by the hash of the public key. Bob’s webserver is unmodified, and doesn’t even know that it’s hidden behind the Tor network.

Alice’s applications also work unchanged—her client interface remains a SOCKS proxy. We encode all of the necessary information into the fully qualified domain name Alice uses when establishing her connection. Location-hidden services use a virtual top level domain called `.onion`: thus hostnames take the form `x.y.onion` where `x` is the authorization cookie and `y` encodes the hash of the public key. Alice’s onion proxy examines addresses; if they’re destined for a hidden server, it decodes the key and starts the rendezvous as described above.

A.2 Previous rendezvous work

Rendezvous points in low-latency anonymity systems were first described for use in ISDN telephony [30, 38]. Later low-latency designs used rendezvous points for hiding location of mobile phones and low-power location trackers [23, 40]. Rendezvous for low-latency Internet connections was suggested in early Onion Routing work [27], but the first published design was by Ian Goldberg [26]. His design differs from ours in three ways. First, Goldberg suggests that Alice should manually hunt down a current location of the service via Gnutella; our approach makes lookup transparent to the user, as well as faster and more robust. Second, in Tor the client and server negotiate session keys via Diffie-Hellman, so plaintext is not exposed even at the rendezvous point. Third, our design minimizes the exposure from running the service, to encourage volunteers to offer introduction and rendezvous services. Tor’s introduction points do not output any bytes to the clients; the rendezvous points don’t know the client or the server, and can’t read the data being transmitted. The indirection scheme is also designed to include authentication/authorization—if Alice doesn’t include the right cookie with her request for service, Bob need not even acknowledge his existence.
